Current practice background

There are three distinct levels of nutrients a plant needs to healthily grow and develop:
- **Primary nutrients**: Nitrogen, phosphorus and potassium (NPK) – needed in large quantities by the plant.
- **Secondary nutrients**: Calcium, magnesium and sulphur – important but smaller quantities required.
- **Micronutrients**: e.g. manganese, zinc, copper, boron, molybdenum etc.

‘Aloy’ products are an efficient answer to micronutrient delivery, allowing an effective supply of minerals with minimal waste. The properties of these formulations mean they are of increasing interest in the agrochemical market, notably because they are often more cost-effective over a season than the more traditional products that are commonly used.

Drawbacks with current micronutrient formulations

Existing methods of mineral supply are typically in the forms of soluble liquids/powders (SLs) or suspension concentrates (SCs).

Generally speaking, soluble salts are fast acting, but difficult to deposit and keep on the leaf. SCs, however, are slow acting but much easier to deposit and keep on the leaf. Both formulations lead to unused product being wasted.

In the case of SL products, wastage is largely due to the high ionic character – giving high surface tension spray solutions. These solutions are resolutely difficult to deposit on leaves, ‘bouncing’ off similar to a balloon. The tight droplets of product that eventually settle on the leaves are slow to dry and don’t absorb quickly through the cuticular wax.

Once the droplet has deposited on the leaf, the plant will emit organic acids, which will react with the metal ions turning them into simple soaps. This will ease the passage through the wax barrier and allow the micronutrients to be absorbed. However, the solution will have poor rainfastness and may be washed away within this time frame.

Another disadvantage of a soluble salt is that modern day spraying practice usually entails more than one (sometimes up to seven) active chemicals being applied at the same time. They can cause physical incompatibilities in the spray tank, especially with highly alkaline solutions or emulsifiable concentrates.

With regard to suspension concentrates, the deposition on the target is much easier – these formulations have a much lower surface tension due to the addition of surfactants. The droplets will therefore stay on the leaf and hence dry more quickly. These surfactants will also soften the cuticular wax meaning the particles will be more effectively affixed to the leaf, and rainfall will therefore not wash off the deposit.

The micronutrient, however, will not be transported to the point of action very quickly due to the low solubility of these formulations. Additionally, suspension concentrates do not cause the sprayer any compatibility problems provided the active ingredients are added in the recommended order.
It is largely accepted that for effective plant growth, the application of micronutrients should be within the first 30 days post crop emergence. Establishing a good root structure is of primary importance in producing a healthy crop that can withstand stress brought on by weather or attack by pests – this is something that can’t always be identified visually from the exterior plant (see Figure 1). Both current SL / SC formulations have problems with helping to establish this biomass – SLs tend to be washed away too soon whilst SCs take too long to be absorbed through the leaves to give the required doses.

**What are ‘Aloy’ formulations and what are their benefits?**

‘Aloy’ is a name used by Safagrow (a Safapac Holdings company) to describe a new concept in micronutrient delivery. These formulations are a hybrid of both a soluble liquid and a suspension concentrate – a class known as suspo emulsions (SEs). More specifically, these are in the form of an insoluble powder component suspended in a dilute metallic salt solution. By combining these two formulation types, Aloy products can reap the benefits of each whilst minimizing product wastage.

Similar to SCs, surfactants are present in Aloy formulations to aid with the suspension of particles; the surface tension of the spray solution is reduced. A better deposition of product on the leaf is resultantly achievable – leading to faster drying of the droplet. This in turn allows for an increased rain fastness whilst the surfactants also soften the leaf cuticular wax layer, which causes a better overall uptake of the micronutrients. The portion of soluble salt present also is low enough not to cause any tank mix problems.

By introducing a small amount of highly soluble salt into SCs in this way, Aloys give the crop an initial ‘boost’. This is particularly important with micronutrients like manganese, where the visual greening of the crop gives the user confidence that it is working. These formulations are more concentrated so have reduced handling, storage and transport costs.

Although the initial direct costs of Aloy formulations may appear high, in fact with less frequent and reduced rates of application a season long campaign could be less expensive than traditional products. The combination of benefits from both types of conventional application methods means Aloy formulations present a solution to many of the problems associated with micronutrient efficacy.
